#### ABSTRACT

**Objectives**: Radiation delivered during computed tomography is a major concern, especially for individuals undergoing repeated screening. We aimed to compare a new ultra-low dose algorithm called *Veo* with the gold standard filtered back projection (FBP) for detecting pulmonary asbestos-related conditions.

Setting: University Hospital CHU G. Montpied, Clermont-Ferrand, France

**Participants**: Asbestos-exposed workers were recruited following referral to screening for asbestos-related conditions. Two acquisitions were performed on a 64-slice computed tomography: the gold standard FBP followed by *Veo* reconstruction.

**Outcome measures**: Two radiologists independently assessed asbestos-related abnormalities, pulmonary nodules, radiation doses, and image quality (noise).

**Results**: We included 27 asbestos-exposed workers ( $63.3\pm6.5$  years with  $11.9\pm9.7$  years of asbestos-exposure). We observed 297 pleural plaques in 20 participants (74%). All patients (100%) had pulmonary nodules, totaling 167 nodules. Detection rates did not differ for pleural plaques (*Veo* 87% vs. FBP 97%, NS), pleural thickening (100% for both) and pulmonary nodules (80% for both). Interstitial abnormalities were depicted less frequently with *Veo* than FBP. False negative and false positive did not exceed 2.7%. Compared with FBP, *Veo* decreased the radiation dose up to 87% (*Veo* 0.23±0.07 vs. FBP 1.83±0.88 mSv, p<0.001). The objective image noise also decreased with *Veo* as much as 23% and signal to noise ratio increased up to 33%.

**Conclusion**: A low dose computed tomography with *Veo* reconstruction substantially reduced radiation. *Veo* compared favorably with FBP in detecting pleural plaques, pleural thickening and pulmonary nodules. However, due to a few false positives and false negatives, *Veo* may be better for following-up patients after initial screening with FBP (ClinicalTrials.gov number: NCT01955018).

Keywords computed tomography, radiation, screening, asbestos, workers, cancer

#### **BMJ Open**

#### Strengths and limitations of this study

Radiation delivered during computed tomography is a major concern, especially for individuals undergoing repeated screening, such as asbestos-exposed workers.

• We provides the first comparison of a new ultra-low dose algorithm called *Veo* ("I see" in Spanish) with the gold standard filtered back projection (FBP) in detecting pulmonary conditions in asbestos-exposed workers.

■ Veo substantially reduces radiation doses, with 87% less radiation delivered than FBP.

• *Veo* compared favorably with FBP acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules; however, due to a few false positives and false negatives, *Veo* may be better for following-up asbestos-exposed workers after initial screening with FBP.

■ Even if the sample size could be perceived as a limitation, the high prevalence of pleural plaques (297, observed in 74% of participants) and pulmonary nodules (167) permitted a robust statistical analysis.

#### 

# INTRODUCTION

Asbestos fibers were intensively used throughout the 20<sup>th</sup> century <sup>1</sup>, and remain prevalent in developing countries.<sup>1</sup> However, asbestos exposure induces a variety of benign and malignant pleural and lung diseases.<sup>2 3</sup> Due to a long latency period between exposure and disease presentation, asbestos-related diseases remain a substantial public health problem.<sup>1</sup> The most common asbestos-induced neoplasm is lung cancer.<sup>2 3</sup> Chest computed tomography (CT) screening has been successfully used in the early detection of lung cancer in asbestos-exposed workers.<sup>4-6</sup> Moreover, thin-section CT is more sensitive than a chest x-ray for detecting early asbestos-related conditions.<sup>7-10</sup> Nevertheless, the use of CT has two main disadvantages: high radiation doses and depiction of incidental abnormalities such as pulmonary nodules in asymptomatic patients. Incidental abnormalities increase the frequency of follow-up by CT and may also psychologically impact on patients. Medical exposure from x-rays represents the major source of man-made irradiation with a large contribution from CT.<sup>11-13</sup> Increased exposure to radiation underpins the consequences of cancer induction.<sup>14</sup> However, reducing CT doses increases image noise from the filtered back projection (FBP) reconstruction. Strategies to reduce radiation exposure include the use of iterative reconstruction algorithms such as "iDose", "100% ASIR" and "IRIS".<sup>15-20</sup> The new algorithm called Veo<sup>TM</sup> (General Electric Healthcare, Milwaukee, MI, USA) decreases the image noise up to 70% compared with the gold standard FBP model, whereas the "100% ASIR" algorithm is only capable of reducing image noise up to 47%.<sup>21</sup> Moreover, Veo ("I see" in Spanish) improves spatial resolution with excellent detection of low and high contrast objects from a CT Dose Index (CTDI<sub>vol</sub>) equal to 0.3 mGy.

Thus, the objective of the present study was to compare *Veo* with the gold standard FBP for detecting pulmonary asbestos-related conditions among workers previously exposed to asbestos. Comparisons included radiation delivered and image quality.

# **METHODS**

#### Patients

Our prospective clinical study received approval from the ethical committee of the University Hospital of Clermont-Ferrand (ClinicalTrials.gov number: NCT01955018). Written informed consent was obtained from all participants for the supplementary acquisition of *Veo* images in addition to their clinically indicated chest CT. Asbestos-exposed workers were recruited following referral to our radiology department for the evaluation of asbestos-related disease between September 2012, and April 2013. Inclusion criteria were being an asbestos-exposed workers, having a chest CT referral from the occupational medicine department, no history of cancer or thoracic surgery, and the absence of other known interstitial pathology.

#### **CT** protocol

CT examinations were performed with a 64-slice CT system (Discovery CT 750HD; GE Healthcare, Milwaukee, WI) and consisted of two successive acquisitions. Each examination, the normal-dose (FBP acquisition) and ultra-low-dose (*Veo* acquisition) spiral CT, was obtained on the entire thorax, at full inspiration with the participant in the supine position. No intravenous contrast material was administered. In accordance with guidelines, standard acquisition was performed with CT parameters adjusted to the participant's body size, including a tube kilovoltage (kV) of 120 (participants weighing 70 kg or less) and 140 (participants weighing more than 70 kg), with milliamperage (mA) equal to the patient's body weight. The other CT parameters were rotation time 0.5 s and pitch 1.375. Image data were reconstructed with FBP algorithm. The *Veo* acquisition was performed with constant CT

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES)

Protected by copyright, including for uses related to text and data mining, Al training, and similar technologies

parameters including: a tube voltage of 100 kV, a tube current of 20 mA, pitch of 0.984 and rotation time 0.4 s. Image data were reconstructed with the *Veo* algorithm.

#### **Interpretation of CT Images**

Each CT acquisition was viewed independently by two experienced radiologists (2 to 7 years of experience). The low-dose images with *Veo* reconstruction were interpreted before the standard CT and on separate weeks to minimize recall bias. The gold standard CT was established by a second and simultaneous reading of the *Veo* and FBP acquisitions by the more experienced radiologist to evaluate the detection and characterization of pleuroparenchymal abnormalities. Because FBP images are benchmark practice, when a lesion was found only on *Veo* images, it was regarded as a false positive.

#### Pleural and parenchymal abnormalities

According to established criteria,<sup>9 22 23</sup> the following asbestos-related pleural and parenchymal abnormalities were recorded as present or absent. Pleural abnormalities considered were:

- Pleural plaques: pleura thickening with no associated parenchymal abnormality. We recorded for each lesion: localization (side, region: anterolateral, posterolateral, diaphragmatic or mediastinum), thickness, and calcification.

- Diffuse pleural thickening: pleural thickening associated with parenchymal abnormalities such as rounded atelectasis and parenchymal bands.<sup>22</sup>

- Pleural effusion is typically asymptomatic, the fluid may be serous or hemorrhagic.<sup>22</sup>

CT features of asbestosis included: 1) subpleural dots and branching opacities, 2) curvilinear subpleural lines, defined as linear opacity within 1 cm of the pleura and parallel to the inner chest wall, 3) areas of ground glass opacities, 4) septal lines and 5) reticulations defined as

single or branching lines 1-2 cm in length in the subpleural parenchyma, 6) honeycombing, defined as cystic air spaces with well-defined walls less than 1 cm diameter.

Presence of nodules was also recorded. We noted for each abnormality: localization (side, table position) and nature (non-solid, part-solid, solid or calcified). To increase sensitivity, nodules were examined by combining maximum intensity projections and millimetric axial CT images.<sup>24</sup>

#### Radiation

Comparisons included the dose length product (DLP) in mGy.cm and effective doses in mSv. Computed conversion factor from DLP to effective dose for adult chest is 0.0146 mSv.mGy<sup>-1</sup>.cm<sup>-1 25</sup>.

#### Quality of FBP and Veo Images

Respiratory artifacts were graded on a three-point scale (1 = negligible, 2 = moderate, 3 = salient). Images noise was studied in the axial and coronal planes. A similar scale was used for subjective image quality in the mediastinum and parenchyma windows. Objective image noise (Standard Deviation) and average CT numbers (in Hounsfield's units) were measured with circular regions of interest (ROI) on different anatomical levels, 10 mm in diameter.<sup>19</sup> ROIs were drawn within the descending thoracic aorta at the level of the left main bronchus, within the tracheal lumen up to the tracheal bifurcation, and on the lung. The signal to noise ratio (SNR) was also calculated using the equation SNR = CT numbers / noise.<sup>26</sup>

#### **Statistical Analysis**

Sample size estimation was based on the number of pleural plaques and nodules. Considering the investigative nature of the study design and because the number of pleural plaques and

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES) .

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES) . Protected by copyright, including for uses related to text and data mining, Al training, and similar technologies.

nodules was not known initially, a sample size estimation was not proposed *a priori* even though a concordance coefficient kappa ( $\kappa$ ) between 0.40 and 0.90 was expected between filtered back projection images and *Veo* images. Therefore, 30 asbestos-exposed workers were predicted to be necessary to reject the null hypothesis "H0:  $\kappa = 0.40$ " vs. "H1:  $\kappa \neq 0.75$ " for a proportion of pleural plaques of 65%, with a statistical power of > 85% and  $\alpha$ =5% (twosided). Finally, the study was conducted to sequentially control the statistical power considering the number of plaques and nodules for each asbestos-exposed worker.<sup>27</sup>

Statistical analysis was performed using Stata software (version 12; Stata-Corp, College Station, Tex., USA). Quantitative variables are expressed as means ± standard deviations (SD). Proportions are expressed as percentage and 95% confidence intervals (CIs). Comparisons in paired situation were realized using paired Student t-test or Wilcoxon test when appropriate for quantitative variables and Stuart-Maxwell test for categorical parameters. Sensitivity, specificity, false positives and false negatives values of Veo were calculated and presented with 95% confidence intervals, in comparison with results from FBP acquisitions. Estimates of sensitivity and specificity were obtained by first estimating the sensitivity and specificity for each patient. Sensitivity and specificity were then estimated by averaging the individual specific estimates across patients. The variance of the estimate was the sample variance divided by the number of patients. General estimated equation models with logit link and working independence correlation structure were also used to estimate sensitivity, taking into account the correlation among the multiple pleural plaques and pulmonary nodules for the same patient. The kappa coefficient was used to measure agreement for categorical parameters and Pearson's correlation coefficient and Lin concordance correlation coefficient for quantitative data. The analyses were completed by using of random-effect models when appropriate to consider within and between participant variability. The tests were two-sided, with a type I error set at  $\alpha$ =0.05.

# **RESULTS**

#### Patients

The flow chart of participants is displayed in Figure 1. Among the 87 asbestos-exposed workers referred to our radiology department, 29 gave their consent and, 27 were retained for analyses. The mean age of volunteers was  $63.3\pm6.5$  years old. The mean duration of occupational exposure was  $11.9\pm9.7$  years.

#### **Radiation dose**

The average DLP was  $16\pm5$  mGy.cm for *Veo* and  $125\pm61$  mGy.cm for FBP. The corresponding average effective doses were  $0.234\pm0.073$  mSv for *Veo* and  $1.825\pm0.876$  mSv for FBP. The dose reduction was calculated to be 87.2% (p<0.001).

#### Quality images assessment

For *Veo* acquisition, respiratory artifacts were graded as "negligible" in 24 cases (89%) for reader 1 and 25 cases (93%) for reader 2, "moderate" in 3 cases (11%) for reader 1 and 2 cases (7%) for reader 2, and no "salient" artifact was recorded. For FBP acquisition, respiratory artifacts were graded as "negligible" in 19 cases (70%) for reader 1 and 24 cases (89%) for reader 2, "moderate" in 7 cases (26%) for reader 1 and 3 cases (11%) for reader 2, and as "salient" in 1 case for reader 1 and in 0 cases for reader 2. *Veo* and FBP did not differ in subjective assessment of respiratory artifacts between the two radiologists (p=0.16 for reader 1 and p=0.65 for reader 2).

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES) .

Protected by copyright, including for uses related to text and data mining, Al training, and similar technologies

Tables 1 and 2 provide results from *subjective* image noise assessed by the two radiologists, average of objective noise data and SNR. The two protocols differed significantly in *objective* image noise. The ultra-low-dose *Veo* acquisition reduced objective image noise from 13 to 23% and increased SNR from 5 to 33% compared with the standard FBP acquisition. However, *subjective* image noise rated higher by the two readers in axial and coronal planes, with the exception of parenchymal analysis in the coronal plane for the reader 1 (Table 1).

#### **Pleural plaques**

A total of 297 pleural plaques (Figure 2) were observed in 20 participants (74%). Detection of plaque did not differ between *Veo* (259; 87%) and FBP (287; 97%) (p=0.10). The agreement for pleural plaques depiction was 84% with a kappa of 0.05. However, when data were examined only for the presence of pleural plaque (yes or no) in patients, agreement increased to 96% ( $\kappa = 0.91$ ).<sup>28 29</sup> Moreover agreement for size measurement (Lin coefficient) was 0.83 (p<0.001) and k coefficient for calcification detection was 0.86.

For one participant, despite a *Veo* acquisition considered normal, FBP acquisition was positive for one isolated plaque.

Simultaneous analysis of *Veo* and FBP acquisitions led us to observe that *Veo* acquisition was responsible for 3 false positives corresponding to intercostal fat or muscles, with 8 false negatives (2.7%).

#### **Pleural thickening**

Diffuse pleural thickening (Figure 2) was present in four patients (14.8%). The detection rate for each technique was 100% with a kappa of 1. No pleural effusion was found.

#### **Parenchymal abnormalities**

#### **BMJ Open**

Parenchymal changes were found in 15 participants (55.6%), including subpleural dots, curvilinear subpleural lines, ground glass opacities, septal lines and reticulations. No honeycombing was found. Table 3 summarizes the prevalence (P), inter-rater agreement ( $\tau$ ) and kappa  $\kappa$  between *Veo* and FBP acquisition, and the sensitivity, specificity, predictive positive value and predictive negative value of *Veo* acquisition for each interstitial abnormality.

#### **Pulmonary nodules**

Pulmonary nodules (Figure 2) were found in all patients, with a total of 167 nodules. All the nodules detected were smaller than 10 mm. No non-solid or part-solid nodules were observed. Among the 167 recorded nodules, the detection rate did not differ (p = 0.98) between *Veo* (134/167) and standard FBP (133/167), with the same 80% detection rate. The agreement between the two techniques for nodules depiction was 60% ( $\kappa = 0.25$ ). Simultaneous analysis of *Veo* and FBP acquisitions led us to observe that *Veo* acquisition was responsible for seven false positives (4%) and four false negatives (2.7%).

#### **Inter-observer agreement**

No difference was observed for the inter-observer agreement (kappa) between the two techniques. Inter-observer agreement was low for pleural plaques detection (0.09 for FBP and 0.10 for *Veo*) and fair for nodule detection (0.34 for FBP and 0.34 for *Veo*). The inter-reader agreements for parenchymal interstitial abnormalities and parenchymal diffuse pleural thickening were not evaluated due to their low prevalence.

#### DISCUSSION

We compared for the first time low-dose CT using *Veo* reconstruction and the gold standard CT using FBP reconstruction to depict asbestos-related abnormalities and pulmonary nodules depiction. The major finding was that *Veo* compared favorably with FBP acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules. However, interstitial parenchymal abnormalities were depicted less frequently in *Veo* than FBP acquisitions. Nevertheless, *Veo* delivered 87% less radiation than FBP.

#### Quality of images

The assessment of image quality showed discordant results. Despite low scanning parameters, the iterative reconstruction method of *Veo* significantly reduced the level of objective noise, but subjective noise parameters increased in comparison with FBP. This discordance may be explained by the novel appearance of *Veo* images requiring adaptation time for the radiologists. Our results are in line with previous results showing a relative noise reduction of 25% obtained from *Veo* (100 kV, 10 mAs) compared with FBP protocol (100 kV, 50-300 mAs).<sup>30</sup>

#### **Pleural plaques**

Pleural plaques corresponding to parietal pleura fibrosis are indicators of asbestos-exposure <sup>7</sup> with a prevalence as high as 60% in previously exposed workers <sup>10 31</sup> and 74% in the current study with highly exposed workers. In France, the detection of pleural plaques results in financial compensation for workers and early retirement. Consequently, pleural plaques are accepted only when results are unequivocal. Atypical plaques will only be considered when they occur bilateraly or in multiple sites, and with typical localization. Due to the three cases

#### **BMJ Open**

of false positive and 8 cases of false negative, the low dose CT with *Veo* reconstruction cannot be used for the first examination, but its use seems possible for patients' follow-up.

#### Diffuse pleural thickening detection

Our results indicated that a low dose scanner with *Veo* reconstruction was comparable with the FBP gold standard for diffuse pleural thickening detection. The prevalence of thickening was rare thus, we could not obtain statistical significance. However, thickening remains of major importance because diagnosis results not only in compensation, but guarantees a lifelong pension. Considering the importance usually noted about these lesions, a *Veo* acquisition should be sufficient in clinical practice.

#### **Parenchymal abnormalities**

Reader sensitivity with *Veo* images was poor for interstitial parenchymal abnormalities. No case of true asbestosis was recorded, but 15 patients had non-specific interstitial abnormalities. However, the detection of interstitial abnormalities may be limited by several factors. First, the study was built for asbestos-related diseases. Recording specifications lacked the details required to comprehensively describe the presence of interstitial abnormalities. Therefore, without systematic records, interstitial abnormalities were likely underestimated. Second, *Veo* was always performed after FBP resulting in an increase of gravity-dependent attenuation in the posterior region which may have masked interstitial abnormalities. Third, the acquisitions were performed in the supine position and acquisitions in the prone position were not always performed when necessary. Subsequently, the posterior region was not analyzed with confidence. Thus, interstitials abnormalities were underestimated in our study.

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES) . Protected by copyright, including for uses related to text and data mining, Al training, and similar technologies.

Asbestosis refers to interstitial fibrosis caused by the deposition of asbestos fibers in the lung. Its prevalence is estimated to be about 5% in asbestos exposed workers.<sup>32</sup> Asbestosis remains difficult to diagnose, particularly in early stages. However, a significant dose-effect relationship exists between the cumulative exposure to asbestos and asbestosis.<sup>33</sup> Asbestosis is usually associated with dyspnea, basilar rales, and changes in pulmonary function with restrictive or mixed restrictive-obstructive patterns, and carbon monoxide diffusion abnormalities. Pulmonary asbestosis was previously diagnosed in 51 of 706 (7%) of asbestos-exposed workers were diagnosed with pulmonary asbestosis. In this study, only 2% of the workers with less than 25 years of cumulative exposure to asbestos were diagnosed with asbestosis using high resolution CT screening.<sup>34</sup> Therefore, CT screening for asbestosis does not seem warranted in workers with low occupational exposure.

#### **Pulmonary nodules**

In our study, all individuals had at least one pulmonary nodule. FBP and *Veo* shared the same detection rate of 80%. However, *Veo* reconstruction is not advised for initial nodules screening due to the 7 false positives and 4 false negatives from the 167 nodules. According to the Fleischner Society guidelines <sup>35</sup>, nodule detection on CT requires specific management. In agreement with our recommendations for pleural plaques detection, *Veo* should be used only for patients' follow-up after a first detection of pulmonary nodules using gold standard CT.

#### Limitations

The sample size could be perceived as a limitation. Limited sample size exacerbated the need for rapid adaptation time by the radiologists with relatively novel images. However,

statistically, the high prevalence of pleural plaques (297, observed in 74% of participants) and pulmonary nodules (167) permitted a robust statistical analysis. Considering these results ( $\kappa =$ 0.91), power seemed satisfactory (80%) to reject the null hypothesis "H0:  $\kappa = 0.4$ " vs. "H1:  $\kappa \neq 0.91$ " with 27 patients. In contrast, parenchymal interstitial abnormalities were rare, precluding sound statistical analyses. Parenchymal interstitial abnormalities suffered from majors limitations due to CT positioning of patients. A further study dedicated to parenchymal interstitial abnormalities should be conducted. Clinically, a current limitation of iterative reconstruction is a long computing time.

# CONCLUSION

A low dose computed tomography with *Veo* reconstruction substantially reduces radiation. Despite an unusual appearance, *Veo* image quality was generally accurate in its diagnosis. Specifically, *Veo* compared favorably with the gold standard filtered back projection acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules. However, due to a few false positives and false negatives, *Veo* may be best used for follow-up of patients after initial screening with filtered back projection.

#### ABSTRACT

**Objectives**: Radiation delivered during computed tomography is a major concern, especially for individuals undergoing repeated screening. We aimed to compare a new ultra-low dose algorithm called *Veo* with the gold standard filtered back projection (FBP) for detecting pulmonary asbestos-related conditions.

Setting: University Hospital CHU G. Montpied, Clermont-Ferrand, France

**Participants**: Asbestos-exposed workers were recruited following referral to screening for asbestos-related conditions. Two acquisitions were performed on a 64-slice computed tomography: the gold standard FBP followed by *Veo* reconstruction.

**Outcome measures**: Two radiologists independently assessed asbestos-related abnormalities, pulmonary nodules, radiation doses, and image quality (noise).

**Results**: We included 27 asbestos-exposed workers ( $63.3\pm6.5$  years with  $11.9\pm9.7$  years of asbestos-exposure). We observed 297 pleural plaques in 20 participants (74%). All patients (100%) had pulmonary nodules, totaling 167 nodules. Detection rates did not differ for pleural plaques (*Veo* 87% vs. FBP 97%, NS), pleural thickening (100% for both) and pulmonary nodules (80% for both). Interstitial abnormalities were depicted less frequently with *Veo* than FBP. False negative and false positive did not exceed 2.7%. Compared with FBP, *Veo* decreased the radiation dose up to 87% (*Veo* 0.23±0.07 vs. FBP 1.83±0.88 mSv, p<0.001). The objective image noise also decreased with *Veo* as much as 23% and signal to noise ratio increased up to 33%.

**Conclusion**: A low dose computed tomography with *Veo* reconstruction substantially reduced radiation. *Veo* compared favorably with FBP in detecting pleural plaques, pleural thickening and pulmonary nodules. These results should be confirmed on a larger sample size before the use of *Veo* in clinical routine practice in asbestos-related conditions, especially regarding the low prevalence of interstitial abnormalities in this study (ClinicalTrials.gov number: NCT01955018).

Keywords computed tomography, radiation, screening, asbestos, workers, cancer

#### **BMJ Open**

Radiation delivered during computed tomography is a major concern, especially for individuals undergoing repeated screening, such as asbestos-exposed workers.

• We provides the first comparison of a new ultra-low dose algorithm called *Veo* ("I see" in Spanish) with the gold standard filtered back projection (FBP) in detecting pulmonary conditions in asbestos-exposed workers.

■ Veo substantially reduces radiation doses, with 87% less radiation delivered than FBP.

Veo compared favorably with FBP acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules; the high prevalence of pleural plaques (297, observed in 74% of participants) and pulmonary nodules (167) permitted a robust statistical analysis.

However, these results should be confirmed on a larger sample size before the use of *Veo* in clinical routine practice in asbestos-related conditions, especially regarding the low prevalence of interstitial abnormalities.

#### 

# INTRODUCTION

Asbestos fibers were intensively used throughout the 20<sup>th</sup> century, and remain prevalent in developing countries.<sup>1</sup> However, asbestos exposure induces a variety of benign and malignant pleural and lung diseases.<sup>2 3</sup> Due to a long latency period between exposure and disease presentation, asbestos-related diseases remain a substantial public health problem.<sup>1</sup> The most common asbestos-induced neoplasm is lung cancer.<sup>2 3</sup> Chest computed tomography (CT) screening has been successfully used in the early detection of lung cancer in asbestos-exposed workers.<sup>4-6</sup> Moreover, thin-section CT is more sensitive than a chest x-ray for detecting early asbestos-related conditions.<sup>7-10</sup> Nevertheless, the use of CT has two main disadvantages: high radiation doses and depiction of incidental abnormalities such as pulmonary nodules in asymptomatic patients. Incidental abnormalities increase the frequency of follow-up by CT and may also psychologically impact on patients. Medical exposure from x-rays represents the major source of man-made irradiation with a large contribution from CT.<sup>11-13</sup> Increased exposure to radiation underpins the consequences of cancer induction.<sup>14</sup> However, reducing CT doses increases image noise from the filtered back projection (FBP) reconstruction. Strategies to reduce radiation exposure include the use of iterative reconstruction algorithms such as "iDose", "100% ASIR" and "IRIS".<sup>15-20</sup> The new algorithm called Veo<sup>TM</sup> (General Electric Healthcare, Milwaukee, MI, USA) decreases the image noise up to 70% compared with the gold standard FBP model, whereas the "100% ASIR" algorithm is only capable of reducing image noise up to 47%.<sup>21</sup> Moreover, Veo ("I see" in Spanish) improves spatial resolution with excellent detection of low and high contrast objects from a CT Dose Index (CTDI<sub>vol</sub>) equal to 0.3 mGy.

Thus, the objective of the present study was to compare *Veo* with the gold standard FBP for detecting pulmonary asbestos-related conditions among workers previously exposed to asbestos. Comparisons included radiation delivered and image quality.

# METHODS

#### Patients

Our clinical observational study received approval from the ethical committee of the University Hospital of Clermont-Ferrand (ClinicalTrials.gov number: NCT01955018). Written informed consent was obtained from all participants for the supplementary acquisition of *Veo* images in addition to their clinically indicated chest CT. Asbestos-exposed workers were recruited following referral to our radiology department for the evaluation of asbestos-related disease between September 2012, and April 2013. Inclusion criteria were being an asbestos-exposed workers, having a chest CT referral from the occupational medicine department, no history of cancer or thoracic surgery, and the absence of other known interstitial pathology.

#### **CT protocol**

CT examinations were performed with a 64-slice CT system (Discovery CT 750HD; GE Healthcare, Milwaukee, WI) and consisted of two successive acquisitions. Each examination, the normal-dose (FBP acquisition) and ultra-low-dose (*Veo* acquisition) spiral CT, was obtained on the entire thorax, at full inspiration with the participant in the supine position. No intravenous contrast material was administered. In accordance with guidelines, standard acquisition was performed with CT parameters adjusted to the participant's body size, including a tube kilovoltage (kV) of 120 (participants weighing 70 kg or less) and 140 (participants weighing more than 70 kg), with milliamperage (mA) equal to the patient's body weight. The other CT parameters were rotation time 0.5 s and pitch 1.375. Image data were

reconstructed with FBP algorithm. The *Veo* acquisition was performed with constant CT parameters including: a tube voltage of 100 kV, a tube current of 20 mA, pitch of 0.984 and rotation time 0.4 s. Image data were reconstructed with the *Veo* algorithm.

#### **Interpretation of CT Images**

Each CT acquisition was viewed independently by two radiologists (2 and 7 years of experience – Drs RB and AR). The low-dose images with *Veo* reconstruction were interpreted before the standard CT and on separate weeks to minimize recall bias. A third simultaneous reading of the *Veo* and FBP acquisitions by the more experienced radiologist (AR) evaluated the concordance of pleuroparenchymal abnormalities between *Veo* and FBP. Because FBP images are benchmark practice, when a lesion was found only on *Veo* images, it was regarded as a false positive.

#### Pleural and parenchymal abnormalities

According to established criteria,<sup>9 22 23</sup> the following asbestos-related pleural and parenchymal abnormalities were recorded as present or absent. Pleural abnormalities considered were:

- Pleural plaques: pleura thickening with no associated parenchymal abnormality. We recorded for each lesion: localization (side, region: anterolateral, posterolateral, diaphragmatic or mediastinum), thickness, and calcification.

- Diffuse pleural thickening: pleural thickening associated with parenchymal abnormalities such as rounded atelectasis and parenchymal bands.<sup>22</sup>

- Pleural effusion is typically asymptomatic, the fluid may be serous or hemorrhagic.<sup>22</sup>

CT features of asbestosis included: 1) subpleural dots and branching opacities, 2) curvilinear subpleural lines, defined as linear opacity within 1 cm of the pleura and parallel to the inner chest wall, 3) areas of ground glass opacities, 4) septal lines and 5) reticulations defined as

single or branching lines 1-2 cm in length in the subpleural parenchyma, 6) honeycombing, defined as cystic air spaces with well-defined walls less than 1 cm diameter.

Presence of nodules was also recorded. We noted for each abnormality: localization (side, table position) and nature (non-solid, part-solid, solid or calcified). To increase sensitivity, nodules were examined by combining maximum intensity projections and millimetric axial CT images.<sup>24</sup>

#### Radiation

Comparisons included the dose length product (DLP) in mGy.cm and effective doses in mSv. Computed conversion factor from DLP to effective dose for adult chest is 0.0146 mSv.mGy<sup>-1</sup>.cm<sup>-1 25</sup>.

#### Quality of FBP and Veo Images

Respiratory artifacts were graded on a three-point scale (1 = negligible, 2 = moderate, 3 = salient). Images noise was studied in the axial and coronal planes. A similar scale was used for subjective image quality in the mediastinum and parenchyma windows. Objective image noise is the mean of the Standard Deviation of the signal intensity (in Hounsfield's units) measured with circular regions of interest (ROI) on different anatomical levels, 10 mm in diameter.<sup>19</sup> ROIs were drawn within the descending thoracic aorta at the level of the left main bronchus, within the tracheal lumen up to the tracheal bifurcation, and on the lung. The signal to noise ratio (SNR) was also calculated using the equation SNR = signal intensity / objective noise.<sup>26</sup>

#### **Statistical Analysis**

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES) .

Protected by copyright, including for uses related to text and data mining, Al training, and similar technologies
Sample size estimation was based on the number of pleural plaques and nodules. Considering the investigative nature of the study design and because the number of pleural plaques and nodules was not known initially, a sample size estimation was not proposed a priori even though a concordance coefficient kappa ( $\kappa$ ) between 0.40 and 0.90 was expected between filtered back projection images and Veo images. Therefore, 30 asbestos-exposed workers were predicted to be necessary to reject the null hypothesis "H0:  $\kappa = 0.40$ " vs. "H1:  $\kappa \neq 0.75$ " for a proportion of pleural plaques of 65%, with a statistical power of > 85% and  $\alpha$ =5% (twosided). Finally, the study was conducted to sequentially control the statistical power considering the number of plaques and nodules for each asbestos-exposed worker.<sup>27</sup> Statistical analysis was performed using Stata software (version 12; Stata-Corp, College Station, Tex., USA). Quantitative variables are expressed as means  $\pm$  standard deviations (SD). Proportions are expressed as percentage and 95% confidence intervals (CIs). Comparisons in paired situation were realized using paired Student t-test or Wilcoxon test when appropriate for quantitative variables and Stuart-Maxwell test for categorical parameters. Sensitivity, specificity, false positives and false negatives values of Veo were calculated and presented with 95% confidence intervals, in comparison with results from FBP acquisitions. Estimates of sensitivity and specificity were obtained by first estimating the sensitivity and specificity for each patient. Sensitivity and specificity were then estimated by averaging the individual specific estimates across patients. The variance of the estimate was the sample variance divided by the number of patients. Generalized estimating equation models with logit link and working independence correlation structure were also used to estimate sensitivity, taking into account the correlation among the multiple pleural plaques and pulmonary nodules for the same patient. The kappa coefficient was used to measure agreement for categorical parameters and Pearson's correlation coefficient and Lin concordance correlation coefficient for quantitative data. The analyses were completed by

#### **BMJ Open**

using of random-effect models when appropriate to consider within and between participant variability. The tests were two-sided, with a type I error set at  $\alpha$ =0.05.

# RESULTS

# Patients

The flow chart of participants is displayed in Figure 1. Among the 87 asbestos-exposed workers referred to our radiology department, 29 gave their consent and, 27 were retained for analyses. The mean age of volunteers was  $63.3\pm6.5$  years old. The mean duration of occupational exposure was  $11.9\pm9.7$  years.

#### **Radiation dose**

The average DLP was  $16\pm5$  mGy.cm for *Veo* and  $125\pm61$  mGy.cm for FBP. The corresponding average effective doses were  $0.234\pm0.073$  mSv for *Veo* and  $1.825\pm0.876$  mSv for FBP. The dose reduction was calculated to be 87.2% (p<0.001).

#### Quality images assessment

For *Veo* acquisition, respiratory artifacts were graded as "negligible" in 24 cases (89%) for reader 1 and 25 cases (93%) for reader 2, "moderate" in 3 cases (11%) for reader 1 and 2 cases (7%) for reader 2, and no "salient" artifact was recorded. For FBP acquisition, respiratory artifacts were graded as "negligible" in 19 cases (70%) for reader 1 and 24 cases (89%) for reader 2, "moderate" in 7 cases (26%) for reader 1 and 3 cases (11%) for reader 2, and as "salient" in 1 case for reader 1 and in 0 cases for reader 2. *Veo* and FBP did not differ

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de l Enseignement Superieur (ABES) . Protected by copyright, including for uses related to text and data mining, Al training, and similar technologies.

in subjective assessment of respiratory artifacts between the two radiologists (p=0.16 for reader 1 and p=0.65 for reader 2).

Tables 1 and 2 provide results from *subjective* image noise assessed by the two radiologists using, average of objective noise data and SNR. The two protocols differed significantly in *objective* image noise. The ultra-low-dose *Veo* acquisition reduced objective image noise from 13 to 23% and increased SNR from 5 to 33% compared with the standard FBP acquisition.

However, the two readers rated higher *subjective* image noise in axial and coronal planes with *Veo* than FBP, with the exception of parenchymal analysis in the coronal plane for the reader 1 (Table 1).

#### **Pleural plaques**

A total of 297 pleural plaques (Figure 2) were observed in 20 participants (74%). Detection of plaques did not differ between *Veo* (259; 87%) and FBP (287; 97%) (p=0.10). Thus, the third simultaneous reading of *Veo* and FBP resulted in the detection of 10 plaques that were not detected during the first reading of FBP images. The agreement for pleural plaques depiction was 84% with a kappa of 0.05. However, when data were examined only for the presence of pleural plaque (yes or no) in patients, agreement increased to 96% ( $\kappa = 0.91$ ).<sup>28 29</sup> Moreover agreement for size measurement (Lin coefficient) was 0.83 (p<0.001) and k coefficient for calcification detection was 0.86.

For one participant, despite a *Veo* acquisition considered normal, FBP acquisition was positive for one isolated plaque.

Simultaneous analysis of *Veo* and FBP acquisitions led us to observe that *Veo* acquisition was responsible for 3 false positives corresponding to intercostal fat or muscles, with 8 false negatives (2.7%).

# **Pleural thickening**

Diffuse pleural thickening (Figure 2) was present in four patients (14.8%). The detection rate for each technique was 100% with a kappa of 1. No pleural effusion was found.

# Parenchymal abnormalities

Parenchymal changes were found in 15 participants (55.6%), including subpleural dots, curvilinear subpleural lines, ground glass opacities, septal lines and reticulations. No honeycombing was found. Table 3 summarizes the prevalence (P), inter-rater agreement ( $\tau$ ) and kappa  $\kappa$  between *Veo* and FBP acquisition, and the sensitivity, specificity, predictive positive value and predictive negative value of *Veo* acquisition for each interstitial abnormality.

#### **Pulmonary nodules**

Pulmonary nodules (Figure 2) were found in all patients, with a total of 167 nodules. All the nodules detected were smaller than 10 mm. No non-solid or part-solid nodules were observed. Among the 167 recorded nodules, the detection rate did not differ (p = 0.98) between *Veo* (134/167) and standard FBP (133/167), with the same 80% detection rate. Thus, the third simultaneous reading of *Veo* and FBP resulted in the detection of 34 nodules that were not detected during the first reading of FBP images. The agreement between the two techniques for nodules depiction was 60% ( $\kappa = 0.25$ ). Simultaneous analysis of *Veo* and FBP acquisitions permitted us to observe that *Veo* acquisition was responsible for seven false positives (4%) and four false negatives (2.7%).

No difference was observed for the inter-observer agreement (kappa) between the two techniques. Inter-observer agreement was low for pleural plaques detection (0.09 for FBP and 0.10 for *Veo*) and fair for nodule detection (0.34 for FBP and 0.34 for *Veo*). The inter-reader agreements for parenchymal interstitial abnormalities and parenchymal diffuse pleural thickening were not evaluated due to their low prevalence.

# DISCUSSION

We compared for the first time low-dose CT using *Veo* reconstruction and the gold standard CT using FBP reconstruction to depict asbestos-related abnormalities and pulmonary nodules depiction. The major finding was that *Veo* compared favorably with FBP acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules. However, interstitial parenchymal abnormalities were depicted less frequently in *Veo* than FBP acquisitions. Nevertheless, *Veo* delivered 87% less radiation than FBP.

# Quality of images

The assessment of image quality showed discordant results. Despite low scanning parameters, the iterative reconstruction method of *Veo* significantly reduced the level of objective noise, but subjective noise parameters increased in comparison with FBP. This discordance may be explained by the novel appearance of *Veo* images requiring adaptation time for the radiologists. Our results are in line with previous results showing a relative noise reduction of 25% obtained from *Veo* (100 kV, 10 mAs) compared with FBP protocol (100 kV, 50-300 mAs).<sup>30</sup>

#### **Pleural plaques**

Pleural plaques corresponding to parietal pleura fibrosis are indicators of asbestos-exposure <sup>7</sup> with a prevalence as high as 60% in previously exposed workers <sup>10 31</sup> and 74% in the current study with highly exposed workers. In France, the detection of pleural plaques results in financial compensation for workers and early retirement. Consequently, pleural plaques are accepted only when results are unequivocal. Atypical plaques will only be considered when they occur bilateraly or in multiple sites, and with typical localization. Due to the three cases of false positive and 8 cases of false negative, the low dose CT with *Veo* reconstruction cannot be used for the first examination, but its use seems possible for patients' follow-up.

# Diffuse pleural thickening detection

Our results indicated that a low dose scanner with *Veo* reconstruction was comparable with the FBP gold standard for diffuse pleural thickening detection. The prevalence of thickening was rare thus, we could not obtain statistical significance. However, thickening remains of major importance because diagnosis results not only in compensation, but guarantees a lifelong pension. Considering the importance usually noted about these lesions, a *Veo* acquisition should be sufficient in clinical practice.

#### **Parenchymal abnormalities**

Reader sensitivity with *Veo* images was poor for interstitial parenchymal abnormalities. No case of true asbestosis was recorded, but 15 patients had non-specific interstitial abnormalities. However, the detection of interstitial abnormalities may be limited by several factors. First, the study was built for asbestos-related diseases. Recording specifications lacked the details required to comprehensively describe the presence of interstitial abnormalities. Therefore, without systematic records, interstitial abnormalities were likely

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES) .

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de Enseignement Superieur (ABES)

Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies

underestimated. Second, *Veo* was always performed after FBP resulting in an increase of gravity-dependent attenuation in the posterior region which may have masked interstitial abnormalities. Third, the acquisitions were performed in the supine position and acquisitions in the prone position were not always performed when necessary. Subsequently, the posterior region was not analyzed with confidence. Thus, interstitials abnormalities were underestimated in our study.

Asbestosis refers to interstitial fibrosis caused by the deposition of asbestos fibers in the lung. Its prevalence is estimated to be about 5% in asbestos exposed workers.<sup>32</sup> Asbestosis remains difficult to diagnose, particularly in early stages. However, a significant dose-effect relationship exists between the cumulative exposure to asbestos and asbestosis.<sup>33</sup> Asbestosis is usually associated with dyspnea, basilar rales, and changes in pulmonary function with restrictive or mixed restrictive-obstructive patterns, and carbon monoxide diffusion abnormalities. Pulmonary asbestosis was previously diagnosed in 51 of 706 (7%) of asbestos-exposed workers.<sup>34</sup> In a previous study, 51 of the 706 (7%) of asbestos-exposed workers were diagnosed with pulmonary asbestosis. In this study, only 2% of the workers with less than 25 years of cumulative exposure to asbestos were diagnosed with asbestosis using high resolution CT screening.<sup>34</sup> Therefore, CT screening for asbestosis does not seem warranted in workers with low occupational exposure.

# **Pulmonary nodules**

In our study, all individuals had at least one pulmonary nodule. FBP and *Veo* shared the same detection rate of 80%. However, *Veo* reconstruction is not advised for initial nodules screening due to the 7 false positives and 4 false negatives from the 167 nodules. According to the Fleischner Society guidelines <sup>35</sup>, nodule detection on CT requires specific management. In agreement with our recommendations for pleural plaques detection, *Veo* should be used

#### **BMJ Open**

only for patients' follow-up after a first detection of pulmonary nodules using gold standard CT.

#### Comparison of Veo with other low-dose algorithms

To date, no studies using other algorithms to reduce radiation exposure have investigated asbestos-related conditions. Thus, because the *Veo* algorithm appears to reduce the more radiation delivered than other low-dose algorithm such as "iDose", "100% ASIR" or "IRIS"<sup>15-20</sup>, we chose only to compare *Veo* with the gold standard FBP.

#### Limitations

The sample size could be perceived as a limitation. Limited sample size exacerbated the need for rapid adaptation time by the radiologists with relatively novel images. However, statistically, the high prevalence of pleural plaques (297, observed in 74% of participants) and pulmonary nodules (167) permitted a robust statistical analysis. Considering these results ( $\kappa =$ 0.91), power seemed satisfactory (80%) to reject the null hypothesis "H0:  $\kappa = 0.4$ " vs. "H1:  $\kappa \neq$ 0.91" with 27 patients. In contrast, parenchymal interstitial abnormalities were rare, precluding sound statistical analyses. Parenchymal interstitial abnormalities suffered from majors limitations due to CT positioning of patients. A further study dedicated to parenchymal interstitial abnormalities should be conducted. Clinically, a current limitation of iterative reconstruction is a long computing time.

# CONCLUSION

A low dose computed tomography with *Veo* reconstruction substantially reduces radiation. Despite an unusual appearance, *Veo* image quality was generally accurate in its diagnosis. Specifically, *Veo* compared favorably with the gold standard filtered back projection

acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules. However, these results should be confirmed on a larger sample size before the use of *Veo* in clinical routine practice in asbestos-related conditions, especially regarding the low prevalence of interstitial abnormalities in this study.

# ABSTRACT

**Objectives**: Radiation delivered during computed tomography is a major concern, especially for individuals undergoing repeated screening. We aimed to compare a new ultra-low dose algorithm called *Veo* with the gold standard filtered back projection (FBP) for detecting pulmonary asbestos-related conditions.

Setting: University Hospital CHU G. Montpied, Clermont-Ferrand, France

**Participants**: Asbestos-exposed workers were recruited following referral to screening for asbestos-related conditions. Two acquisitions were performed on a 64-slice computed tomography: the gold standard FBP followed by *Veo* reconstruction.

**Outcome measures**: Two radiologists independently assessed asbestos-related abnormalities, pulmonary nodules, radiation doses, and image quality (noise).

**Results**: We included 27 asbestos-exposed workers ( $63.3\pm6.5$  years with  $11.9\pm9.7$  years of asbestos-exposure). We observed 297 pleural plaques in 20 participants (74%). All patients (100%) had pulmonary nodules, totaling 167 nodules. Detection rates did not differ for pleural plaques (*Veo* 87% vs. FBP 97%, NS), pleural thickening (100% for both) and pulmonary nodules (80% for both). Interstitial abnormalities were depicted less frequently with *Veo* than FBP. False negative and false positive did not exceed 2.7%. Compared with FBP, *Veo* decreased the radiation dose up to 87% (*Veo* 0.23±0.07 vs. FBP 1.83±0.88 mSv, p<0.001). The objective image noise also decreased with *Veo* as much as 23% and signal to noise ratio increased up to 33%.

**Conclusion**: A low dose computed tomography with *Veo* reconstruction substantially reduced radiation. *Veo* compared favorably with FBP in detecting pleural plaques, pleural thickening and pulmonary nodules. However, due to a few false positives and false negatives, *Veo* may be better for following up patients after initial screening with FBP\_These results should be confirmed on a larger sample size before the use of *Veo* in clinical routine practice- in asbestos-related conditions, especially regarding the low prevalence of interstitial abnormalities in this study (ClinicalTrials.gov number: NCT01955018).

#### Strengths and limitations of this study

Radiation delivered during computed tomography is a major concern, especially for individuals undergoing repeated screening, such as asbestos-exposed workers.

• We provides the first comparison of a new ultra-low dose algorithm called *Veo* ("I see" in Spanish) with the gold standard filtered back projection (FBP) in detecting pulmonary conditions in asbestos-exposed workers.

■ Veo substantially reduces radiation doses, with 87% less radiation delivered than FBP.

■ *Veo* compared favorably with FBP acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules; <u>t</u>; however, due to a few false positives and false negatives, *Veo* may be better for following up asbestos exposed workers after initial screening with FBP.

**Even if the sample size could be perceived as a limitation, the high prevalence of pleural** plaques (297, observed in 74% of participants) and pulmonary nodules (167) permitted a robust statistical analysis.

■ However, -these results should be confirmed on a larger sample size before the use of <u>Veo</u>

in clinical routine practice in asbestos-related conditions, especially regarding the low prevalence of interstitial abnormalities.

# INTRODUCTION

Asbestos fibers were intensively used throughout the  $20^{\text{th}}$  century  $\frac{1}{4}$ , and remain prevalent in developing countries.<sup>1</sup> However, asbestos exposure induces a variety of benign and malignant pleural and lung diseases.<sup>2,3</sup> Due to a long latency period between exposure and disease presentation, asbestos-related diseases remain a substantial public health problem.<sup>1</sup> The most common asbestos-induced neoplasm is lung cancer.<sup>2 3</sup> Chest computed tomography (CT) screening has been successfully used in the early detection of lung cancer in asbestos-exposed workers.<sup>4-6</sup> Moreover, thin-section CT is more sensitive than a chest x-ray for detecting early asbestos-related conditions,<sup>7-10</sup> Nevertheless, the use of CT has two main disadvantages: high radiation doses and depiction of incidental abnormalities such as pulmonary nodules in asymptomatic patients. Incidental abnormalities increase the frequency of follow-up by CT and may also psychologically impact on patients. Medical exposure from x-rays represents the major source of man-made irradiation with a large contribution from CT,<sup>11-13</sup> Increased exposure to radiation underpins the consequences of cancer induction.<sup>14</sup> However, reducing CT doses increases image noise from the filtered back projection (FBP) reconstruction. Strategies to reduce radiation exposure include the use of iterative reconstruction algorithms such as "iDose", "100% ASIR" and "IRIS".<sup>15-20</sup> The new algorithm called Veo<sup>™</sup> (General Electric Healthcare, Milwaukee, MI, USA) decreases the image noise up to 70% compared with the gold standard FBP model, whereas the "100% ASIR" algorithm is only capable of reducing image noise up to 47%,<sup>21</sup> Moreover, Veo ("I see" in Spanish) improves spatial resolution with excellent detection of low and high contrast objects from a CT Dose Index (CTDIvol) equal to 0.3 mGy.

Thus, the objective of the present study was to compare *Veo* with the gold standard FBP for detecting pulmonary asbestos-related conditions among workers previously exposed to asbestos. Comparisons included radiation delivered and image quality.

# METHODS

#### Patients

Our prospective-clinical observational study received approval from the ethical committee of the University Hospital of Clermont-Ferrand (ClinicalTrials.gov number: NCT01955018). Written informed consent was obtained from all participants for the supplementary acquisition of *Veo* images in addition to their clinically indicated chest CT. Asbestos-exposed workers were recruited following referral to our radiology department for the evaluation of asbestos-related disease between September 2012, and April 2013. Inclusion criteria were being an asbestos-exposed workers, having a chest CT referral from the occupational medicine department, no history of cancer or thoracic surgery, and the absence of other known interstitial pathology.

#### **CT protocol**

CT examinations were performed with a 64-slice CT system (Discovery CT 750HD; GE Healthcare, Milwaukee, WI) and consisted of two successive acquisitions. Each examination, the normal-dose (FBP acquisition) and ultra-low-dose (*Veo* acquisition) spiral CT, was obtained on the entire thorax, at full inspiration with the participant in the supine position. -No intravenous contrast material was administered. In accordance with guidelines, standard acquisition was performed with CT parameters adjusted to the participant's body size, including a tube kilovoltage (kV) of 120 (participants weighing 70 kg or less) and 140 (participants weighing more than 70 kg), with milliamperage (mA) equal to the patient's body weight. The other CT parameters were rotation time 0.5 s and pitch 1.375. Image data were

reconstructed with FBP algorithm. The *Veo* acquisition was performed with constant CT parameters including: a tube voltage of 100 kV, a tube current of 20 mA, pitch of 0.984 and rotation time 0.4 s. Image data were reconstructed with the *Veo* algorithm.

#### **Interpretation of CT Images**

Each CT acquisition was viewed independently by two experienced-radiologists (2 and to-7 years of experience – Drs RB and AR). The low-dose images with *Veo* reconstruction were interpreted before the standard CT and on separate weeks to minimize recall bias. A third The gold standard CT was established by a second and simultaneous reading of the *Veo* and FBP acquisitions by the more experienced radiologist (AR) to evaluated the concordance detection and characterization of pleuroparenchymal abnormalities between *Veo* and FBP. Because FBP images are benchmark practice, when a lesion was found only on *Veo* images, it was regarded as a false positive.

#### Pleural and parenchymal abnormalities

According to established criteria, <sup>9 22 23</sup> the following asbestos-related pleural and parenchymal abnormalities were recorded as present or absent. Pleural abnormalities considered were: - Pleural plaques: pleura thickening with no associated parenchymal abnormality. We recorded for each lesion: localization (side, region: anterolateral, posterolateral, diaphragmatic or mediastinum), thickness, and calcification.

- Diffuse pleural thickening: pleural thickening associated with parenchymal abnormalities such as rounded atelectasis and parenchymal bands<sup>22</sup>

- Pleural effusion is typically asymptomatic, the fluid may be serous or hemorrhagic<sup>22</sup> CT features of asbestosis included: 1) subpleural dots and branching opacities, 2) curvilinear subpleural lines, defined as linear opacity within 1 cm of the pleura and parallel to the inner Formatted: Font: Italic

Field Code Changed

chest wall, 3) areas of ground glass opacities, 4) septal lines and 5) reticulations defined as					
single or branching lines 1-2 cm in length in the subpleural parenchyma, 6) honeycombing,					
defined as cystic air spaces with well-defined walls less than 1 cm diameter.					
Presence of nodules was also recorded. We noted for each abnormality: localization (side,					
table position) and nature (non-solid, part-solid, solid or calcified). To increase sensitivity,					
nodules were examined by combining maximum intensity projections and millimetric axial					
CT images <sup>24</sup>					

#### Radiation

Comparisons included the dose length product (DLP) in mGy.cm and effective doses in mSv.	
Computed conversion factor from DLP to effective dose for adult chest is 0.0146 mSv.mGy <sup>-</sup>	
<sup>1</sup> .cm <sup>-1</sup> <sup>25</sup> .	

#### Quality of FBP and Veo Images

Respiratory artifacts were graded on a three-point scale (1 = negligible, 2 = moderate, 3 = salient). Images noise was studied in the axial and coronal planes. A similar scale was used for subjective image quality in the mediastinum and parenchyma windows. Objective image noise is the mean of the (Standard Deviation) of the signal intensity and average CT numbers (in Hounsfield's units) were measured with circular regions of interest (ROI) on different anatomical levels, 10 mm in diameter, <sup>19</sup> ROIs were drawn within the descending thoracic aorta at the level of the left main bronchus, within the tracheal lumen up to the tracheal bifurcation, and on the lung. The signal to noise ratio (SNR) was also calculated using the equation SNR = signal intensityCT numbers / objective noise, <sup>26</sup>

#### **Statistical Analysis**

Sample size estimation was based on the number of pleural plaques and nodules. Considering the investigative nature of the study design and because the number of pleural plaques and nodules was not known initially, a sample size estimation was not proposed a priori even though a concordance coefficient kappa ( $\kappa$ ) between 0.40 and 0.90 was expected between filtered back projection images and Veo images. Therefore, 30 asbestos-exposed workers were predicted to be necessary to reject the null hypothesis "H0:  $\kappa = 0.40$ " vs. "H1:  $\kappa \neq 0.75$ " for a proportion of pleural plaques of 65%, with a statistical power of > 85% and  $\alpha$ =5% (twosided). Finally, the study was conducted to sequentially control the statistical power considering the number of plaques and nodules for each asbestos-exposed worker.<sup>27</sup> Statistical analysis was performed using Stata software (version 12; Stata-Corp, College Station, Tex., USA). Quantitative variables are expressed as means  $\pm$  standard deviations (SD). Proportions are expressed as percentage and 95% confidence intervals (CIs). Comparisons in paired situation were realized using paired Student t-test or Wilcoxon test when appropriate for quantitative variables and Stuart-Maxwell test for categorical parameters. Sensitivity, specificity, false positives and false negatives values of Veo were calculated and presented with 95% confidence intervals, in comparison with results from FBP acquisitions. Estimates of sensitivity and specificity were obtained by first estimating the sensitivity and specificity for each patient. Sensitivity and specificity were then estimated by averaging the individual specific estimates across patients. The variance of the estimate was the sample variance divided by the number of patients. Generalized estimatinged equation models with logit link and working independence correlation structure were also used to estimate sensitivity, taking into account the correlation among the multiple pleural plaques and pulmonary nodules for the same patient. The kappa coefficient was used to measure agreement for categorical parameters and Pearson's correlation coefficient and Lin concordance correlation coefficient for quantitative data. The analyses were completed by

Field Code Changed

using of random-effect models when appropriate to consider within and between participant variability. The tests were two-sided, with a type I error set at  $\alpha$ =0.05.

#### RESULTS

#### Patients

The flow chart of participants is displayed in Figure 1. Among the 87 asbestos-exposed workers referred to our radiology department, 29 gave their consent and, 27 were retained for analyses. The mean age of volunteers was  $63.3\pm6.5$  years old. The mean duration of occupational exposure was  $11.9\pm9.7$  years.

#### **Radiation dose**

The average DLP was  $16\pm5$  mGy.cm for *Veo* and  $125\pm61$  mGy.cm for FBP. The corresponding average effective doses were  $0.234\pm0.073$  mSv for *Veo* and  $1.825\pm0.876$  mSv for FBP. The dose reduction was calculated to be 87.2% (p<0.001).

#### Quality images assessment

For *Veo* acquisition, respiratory artifacts were graded as "negligible" in 24 cases (89%) for reader 1 and 25 cases (93%) for reader 2, "moderate" in 3 cases (11%) for reader 1 and 2 cases (7%) for reader 2, and no "salient" artifact was recorded. For FBP acquisition, respiratory artifacts were graded as "negligible" in 19 cases (70%) for reader 1 and 24 cases (89%) for reader 2, "moderate" in 7 cases (26%) for reader 1 and 3 cases (11%) for reader 2, and as "salient" in 1 case for reader 1 and in 0 cases for reader 2. *Veo* and FBP did not differ

in subjective assessment of respiratory artifacts between the two radiologists (p=0.16 for reader 1 and p=0.65 for reader 2).

Tables 1 and 2 provide results from *subjective* image noise assessed by the two radiologists <u>using</u>, average of objective noise data and SNR. The two protocols differed significantly in *objective* image noise. The ultra-low-dose *Veo* acquisition reduced objective image noise from 13 to 23% and increased SNR from 5 to 33% compared with the standard FBP acquisition.

However, <u>the two readers rated higher</u> *subjective* image noise <del>rated higher by the two readers</del> in axial and coronal planes <u>with *Veo* than FBP</u>, with the exception of parenchymal analysis in the coronal plane for the reader 1 (Table 1).

#### **Pleural plaques**

A total of 297 pleural plaques (Figure 2) were observed in 20 participants (74%). Detection of plaques did not differ between *Veo* (259; 87%) and FBP (287; 97%) (p=0.10). Thus, the third simultaneous reading of *Veo* and FBP resulted in the detection of 10 plaques that were not detected during the first reading of FBP images. The agreement for pleural plaques depiction was 84% with a kappa of 0.05. However, when data were examined only for the presence of pleural plaque (yes or no) in patients, agreement increased to 96% ( $\kappa = 0.91$ )<sup>28 29</sup> Moreover agreement for size measurement (Lin coefficient) was 0.83 (p<0.001) and k coefficient for calcification detection was 0.86.

For one participant, despite a *Veo* acquisition considered normal, FBP acquisition was positive for one isolated plaque.

Simultaneous analysis of *Veo* and FBP acquisitions led us to observe that *Veo* acquisition was responsible for 3 false positives corresponding to intercostal fat or muscles, with 8 false negatives (2.7%).

-- Formatted: Font: Not Italic

Field Code Changed

Formatted: Font: Italic

Field Code Changed

#### **Pleural thickening**

Diffuse pleural thickening (Figure 2) was present in four patients (14.8%). The detection rate for each technique was 100% with a kappa of 1. No pleural effusion was found.

#### Parenchymal abnormalities

Parenchymal changes were found in 15 participants (55.6%), including subpleural dots, curvilinear subpleural lines, ground glass opacities, septal lines and reticulations. No honeycombing was found. Table 3 summarizes the prevalence (P), inter-rater agreement ( $\tau$ ) and kappa  $\kappa$  between *Veo* and FBP acquisition, and the sensitivity, specificity, predictive positive value and predictive negative value of *Veo* acquisition for each interstitial abnormality.

#### **Pulmonary nodules**

Pulmonary nodules (Figure 2) were found in all patients, with a total of 167 nodules. All the nodules detected were smaller than 10 mm. No non-solid or part-solid nodules were observed. Among the 167 recorded nodules, the detection rate did not differ (p = 0.98) between *Veo* (134/167) and standard FBP (133/167), with the same 80% detection rate. Thus, the third simultaneous reading of *Veo* and FBP resulted in the detection of 34 nodules that were not detected during the first reading of FBP images.-. The agreement between the two techniques for nodules depiction was 60% ( $\kappa = 0.25$ ). Simultaneous analysis of *Veo* and FBP acquisitions permitted led-us to observe that *Veo* acquisition was responsible for seven false positives (4%) and four false negatives (2.7%).

#### **Inter-observer agreement**

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de

Enseignement Superieur

(ABES)

data mining, Al training, and similar technologies

Protected by copyright, including for uses related to text

No difference was observed for the inter-observer agreement (kappa) between the two techniques. Inter-observer agreement was low for pleural plaques detection (0.09 for FBP and 0.10 for *Veo*) and fair for nodule detection (0.34 for FBP and 0.34 for *Veo*). The inter-reader agreements for parenchymal interstitial abnormalities and parenchymal diffuse pleural thickening were not evaluated due to their low prevalence.

## DISCUSSION

We compared for the first time low-dose CT using *Veo* reconstruction and the gold standard CT using FBP reconstruction to depict asbestos-related abnormalities and pulmonary nodules depiction. The major finding was that *Veo* compared favorably with FBP acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules. However, interstitial parenchymal abnormalities were depicted less frequently in *Veo* than FBP acquisitions. Nevertheless, *Veo* delivered 87% less radiation than FBP.

#### Quality of images

The assessment of image quality showed discordant results. Despite low scanning parameters, the iterative reconstruction method of *Veo* significantly reduced the level of objective noise, but subjective noise parameters increased in comparison with FBP. This discordance may be explained by the novel appearance of *Veo* images requiring adaptation time for the radiologists. Our results are in line -with previous results showing a relative noise reduction of 25% obtained from *Veo* (100 kV, 10 mAs) compared with FBP protocol (100 kV, 50-300 mAs).<sup>30</sup>

#### **Pleural plaques**

Pleural plaques corresponding to parietal pleura fibrosis are indicators of asbestos-exposure  ${}^{7}_{*-}$  with a prevalence as high as 60% in previously exposed workers  ${}^{10 31}_{*-*}$  and 74% in the current study with highly exposed workers. In France, the detection of pleural plaques results in financial compensation for workers and early retirement. Consequently, pleural plaques are accepted only when results are unequivocal. Atypical plaques will only be considered when they occur bilateraly or in multiple sites, and with typical localization. Due to the three cases of false positive and 8 cases of false negative, the low dose CT with *Veo* reconstruction cannot be used for the first examination, but its use seems possible for patients' follow-up.

#### Diffuse pleural thickening detection

Our results indicated that a low dose scanner with *Veo* reconstruction was comparable with the FBP gold standard for diffuse pleural thickening detection. The prevalence of thickening was rare thus, we could not obtain statistical significance. However, thickening remains of major importance because diagnosis results not only in compensation, but guarantees a lifelong pension. Considering the importance usually noted about these lesions, a *Veo* acquisition should be sufficient in clinical practice.

#### **Parenchymal abnormalities**

Reader sensitivity with *Veo* images was poor for interstitial parenchymal abnormalities. No case of true asbestosis was recorded, but 15 patients had non-specific interstitial abnormalities. However, the detection of interstitial abnormalities may be limited by several factors. First, the study was built for asbestos-related diseases. Recording specifications lacked the details required to comprehensively describe the presence of interstitial abnormalities. Therefore, without systematic records, interstitial abnormalities were likely

data mining

Al training, and similar technologies

Protected by copyright, including for uses related to text and

underestimated. Second, *Veo* was always performed after FBP resulting in an increase of gravity-dependent attenuation in the posterior region which may have masked interstitial abnormalities. Third, the acquisitions were performed in the supine position and acquisitions in the prone position were not always performed when necessary. Subsequently, the posterior region was not analyzed with confidence. Thus, interstitials abnormalities were underestimated in our study.

Asbestosis refers to interstitial fibrosis caused by the deposition of asbestos fibers in the lung. Its prevalence is estimated to be about 5% in asbestos exposed workers, <sup>32</sup> Asbestosis remains difficult to diagnose, particularly in early stages. However, a significant dose-effect relationship exists between the cumulative exposure to asbestos and asbestosis, <sup>33</sup> Asbestosis is usually associated with dyspnea, basilar rales, and changes in pulmonary function with restrictive or mixed restrictive-obstructive patterns, and carbon monoxide diffusion abnormalities. Pulmonary asbestosis was previously diagnosed in 51 of 706 (7%) of asbestos-exposed workers were diagnosed with pulmonary asbestosis. In this study, only 2% of the workers with less than 25 years of cumulative exposure to asbestos were diagnosed with asbestosis using high resolution CT screening, <sup>34</sup> Therefore, CT screening for asbestosis does not seem warranted in workers with low occupational exposure.

#### **Pulmonary nodules**

In our study, all individuals had at least one pulmonary nodule. FBP and *Veo* shared the same detection rate of 80%. However, *Veo* reconstruction is not advised for initial nodules screening due to the 7 false positives and 4 false negatives from the 167 nodules. According to the Fleischner Society guidelines  $^{35}_{*-}$ , nodule detection on CT requires specific management. In agreement with our recommendations for pleural plaques detection, *Veo* should be used

Field Code Changed

only for patients' follow-up after a first detection of pulmonary nodules using gold standard CT.

Comparison of *Veo* with other low-dose algorithms To date, no studies using other algorithms to reduce radiation exposure have investigated asbestos-related conditions. Thus, because the *Veo* algorithm appears to reduce the more radiation delivered than other low-dose algorithm such as "iDose", "100% ASIR" or "IRIS"<sup>15-</sup> <sup>20</sup>, we chose only to compare <u>Veo</u> with the gold standard FBP.

#### Limitations

The sample size could be perceived as a limitation. Limited sample size exacerbated the need for rapid adaptation time by the radiologists with relatively novel images. However, statistically, the high prevalence of pleural plaques (297, observed in 74% of participants) and pulmonary nodules (167) permitted a robust statistical analysis. Considering these results ( $\kappa =$ 0.91), power seemed satisfactory (80%) to reject the null hypothesis "H0:  $\kappa = 0.4$ " vs. "H1:  $\kappa \neq 0.91$ " with 27 patients. In contrast, parenchymal interstitial abnormalities were rare, precluding sound statistical analyses. Parenchymal interstitial abnormalities suffered from majors limitations due to CT positioning of patients. A further study dedicated to parenchymal interstitial abnormalities should be conducted. Clinically, a current limitation of iterative reconstruction is a long computing time.

#### CONCLUSION

A low dose computed tomography with *Veo* reconstruction substantially reduces radiation. Despite an unusual appearance, *Veo* image quality was generally accurate in its diagnosis.

Specifically, *Veo* compared favorably with the gold standard filtered back projection acquisitions in detecting pleural plaques, diffuse pleural thickening and pulmonary nodules. However, due to a few false positives and false negatives, *Veo* may be best used for follow up of patients after initial screening with filtered back projection.these results should be confirmed on a larger sample size before the use of *Veo* in clinical routine practice in asbestos-related conditions, especially regarding the low prevalence of interstitial abnormalities in this study.

## STARD checklist for reporting of studies of diagnostic accuracy

(version January 2003)

Section and Topic	Item		On page #
	#	The difference of the second second second second MacCill	
KEYWORDS	1	Identify the article as a study of diagnostic accuracy (recommend MeSH heading 'sensitivity and specificity').	1
INTRODUCTION	2	State the research questions or study aims, such as estimating diagnostic accuracy or comparing accuracy between tests or across participant	3
METHODS		groups.	
Participanto	2	The study population: The inclusion and exclusion criterial setting and	1
	5	locations where data were collected.	4
	4	Participant recruitment: Was recruitment based on presenting symptoms, results from previous tests, or the fact that the participants had received the index tests or the reference standard?	4
	5	Participant sampling: Was the study population a consecutive series of participants defined by the selection criteria in item 3 and 4? If not,	Yes (4)
	6	Data collection: Was data collection planned before the index test and	Prochoctivo: coo
	0	reference standard were performed (prospective study) or after (retrospective study)?	page 4 and stats page 7
Test methods	7	The reference standard and its rationale.	7
	8	Technical specifications of material and methods involved including how and when measurements were taken, and/or cite references for index tests and reference standard.	4 to 6
	9	Definition of and rationale for the units, cut-offs and/or categories of the results of the index tests and the reference standard.	4 to 6
	10	The number, training and expertise of the persons executing and reading	Page 5:
		the index tests and the reference standard.	Interpretation of CT Images
	11	Whether or not the readers of the index tests and reference standard were blind (masked) to the results of the other test and describe any other clinical information available to the readers.	Page 5: Interpretation of CT Images
Statistical methods	12	Methods for calculating or comparing measures of diagnostic accuracy, and the statistical methods used to quantify uncertainty (e.g. 95% confidence intervals).	7
	13	Methods for calculating test reproducibility, if done.	NA
RESULTS			
Participants	14	When study was performed, including beginning and end dates of recruitment.	4: between September 2012, and April 2013
	15	Clinical and demographic characteristics of the study population (at least information on age, gender, spectrum of presenting symptoms).	8
	16	The number of participants satisfying the criteria for inclusion who did or did not undergo the index tests and/or the reference standard; describe why participants failed to undergo either test (a flow diagram is strongly recommended).	8 and figure 3 flow chart
Test results	17	Time-interval between the index tests and the reference standard, and any treatment administered in between.	Simultaneously: see CT protocol pages 6-7
	18	Distribution of severity of disease (define criteria) in those with the target condition; other diagnoses in participants without the target condition.	9-10 if applicable
	19	A cross tabulation of the results of the index tests (including indeterminate and missing results) by the results of the reference standard; for continuous results, the distribution of the test results by the results of the reference standard.	See tables
	20	Any adverse events from performing the index tests or the reference standard.	Impossible to have an adverse event with Veo
Estimates	21	Estimates of diagnostic accuracy and measures of statistical uncertainty (e.g. 95% confidence intervals).	See limitations p14 and p9-10

BMJ Open: first published as 10.1136/bmjopen-2014-004980 on 30 May 2014. Downloaded from http://bmjopen.bmj.com/ on June 13, 2025 at Agence Bibliographique de I Enseignement Superieur (ABES) . Protected by copyright, including for uses related to text and data mining, Al training, and similar technologies.

## **BMJ Open**

	22	How indeterminate results, missing data and outliers of the index tests were handled.	Excluded: page 8 and flow chart figure 3
	23	Estimates of variability of diagnostic accuracy between subgroups of	NA
		participants, readers or centers, if done.	
DISCUSSION	24	Estimates of test reproducibility, if done.	NA Data 12
DISCUSSION		Discuss the clinical applicability of the study findings.	Page 13
